1 Objective

Choose some function g() in R, either built-in to base R or in a CRAN package, to parallelize. Do so in Snow, OpenMP and CUDA (or substitute Thrust for either CUDA or OpenMP, but not both), and run timing tests.

2 Function

We chose to parallelize the function combn() from the "combinat" package in CRAN.

2.1 Description

Taken from the official documentation:[1]

"Generate all combinations of the elements of x taken m at a time. If x is a positive integer, returns all combinations of the elements of seq(x) taken m at a time. If argument "fun" is not null, applies a function given by the argument to each point. If simplify is FALSE, returns a list; else returns a vector or an array. "..." are passed unchanged to function given by argument fun, if any."

2.2 Why Speedups Are Possible

We have tried combn(), which has the inputs combn(x, m, fun=NULL, simplify=TRUE, ...), with different inputs for the vector x and value m. We noticed that combn() became quite slow once x had a size numbering around 100 or higher and m around 5 or higher, taking several minutes to compute (but not print) its results. We think that we can achieve speedups by dividing the input x equally among the threads/nodes, and parallelizing the work of creating the output matrix or list. The goal is to speed up the function, which, based on its source code, currently computes combinations serially.

3 Parallelization

3.1 OpenMP

The C++ OpenMP program is called through R via .Call() using the Rcpp interface. The function combnomp() accepts the same input arguments as the original function combn() from the CRAN package. combnomp() can also handle the same types of valid inputs (see Section 2.1), and through new optional arguments, also allows the user to decide on a scheduling policy and chunk size.

Usage:

```
combnomp <- function(x, m, fun = NULL, simplify = TRUE, sched = NULL,
chunksize = NULL, ...)</pre>
```

where x is the input vector of integers and/or characters, m is number of elements per combination fun is the function to be applied to the resulting output, simplify indicates whether the output must be printed as a matrix (set to TRUE) or as a list (set to FALSE), sched is the scheduling policy (static, dynamic, or guided; default is static), and chunksize is the chunk size for the scheduling policies (default is 1), and ... are the parameters for fun.

Code highlights:

- Load balancing algorithm (lines 101 106 of combn-omp.cpp, described in the next section)
- No critical sections or barriers (except for the implicit barrier after the parallel pragma)

Other notes:

• Similar to the original function, the OpenMP implementation has a limit on the input/output size. The program terminates if R decides that it cannot allocate enough space for the program to successfully run. The max size of x depends on the value of m.

3.1.1 Load Balancing

Good load balancing is very critical to our program because for each element i in the input vector x, the number of combinations that can be generated with x_i is larger than that with x_{i+1} . A naive task distribution without proper load balancing could heavily skew the distribution of the workload for each thread. For example, directly assigning an x_i for each thread will result in the threads with lower id's generating far more combinations (thus, more work) than threads with higher id's.

In order to compensate for the load imbalance, the assignment of tasks to the threads was done in a wrap around manner [2]. Using this method, for the first distribution, each thread will work on the element indexed in the same value as their id (e.g. thread 0 on x[0], thread 1 on x[1], and so on). Then, the following distribution depends on the total number of threads, the id of each thread, and the index of its previous assignment. With nth corresponding to the total number of threads and me corresponding to the thread id, the assignment following the initial distribution is determined using the equation:

$$next_task = prev_task + 2 * (nth - me - 1) + 1 \tag{1}$$

The distribution that will then follow the above depends on the id of each thread and the index of the previous task assigned to that particular thread. This next distribution is determined by the equation:

$$next_task = prev_task + 2 * me + 1 \tag{2}$$

The succeeding distributions alternate in using the two equations until the last distribution, which is for n - m + 1, or the last x_i that can form a combination of size m together with

the elements succeeding it. In this algorithm, each thread knows which indexes in x to generate combinations for. The threads do not need to communicate with each other as they work on their tasks, avoiding huge overhead especially for large values of n.

3.1.2 Chunk Size

The equations from the section above implicitly defines the chunk size so that each thread gets assigned roughly the same number x_i 's to work on. It is essentially the number of times task distributions occur in the load balance algorithm, which is roughly (n - m + 1)/nth.

3.1.3 Scheduling Policies

The load balancing algorithm described in Section 3.1.1 implements a static scheduling policy since the threads are assigned specific tasks and only work on the tasks assigned to them. For the purposes of timing comparisons, additional optional arguments sched and chunksize were added to the function in order to test the speed of the program for the other scheduling policies, namely dynamic and guided. If both arguments are not provided (or set as NULL), the program defaults to the static scheduling policy using the load balancing algorithm. If either dynamic or guided is set, the program uses OpenMP's built-in schedule clause to distribute the tasks to the threads. If chunksize is not provided, the program sets it to the default chunk size of 1.

We performed various tests using the three scheduling policies and experimented with different chunk sizes (for dynamic and guided). It was clear that the load balancing algorithm using static scheduling was the fastest. It eliminates the communication overhead of the dynamic and guided scheduling policies since the threads don't have to repeatedly access the task farm for work, and idleness is still reduced because of the way the tasks are distributed among the threads.

Hence, the static method is the one compared to the original function in the timing comparisons and analysis.

3.1.4 Cache and Other Performance Tuning Considerations

The following performance tuning applies only to the load balancing algorithm described in Section 3.1.1.

- Avoiding instances of false sharing: In order to avoid instances of false sharing (and the resulting cache coherence overheads), we avoided having shared data that could be modified by multiple threads. The data frequently accessed and shared by the threads in the program, such as the input and position vectors are read-only data. Hence, cache lines are not invalidated whenever data from these vectors are accessed. The main shared data structure that is modified by all threads is the output matrix, but the threads never have to perform any read on this data.
- Synchronization overhead: The threads are made to work as independent of each other as possible. The only synchronization occurs implicitly at the end of the parallel pragma.

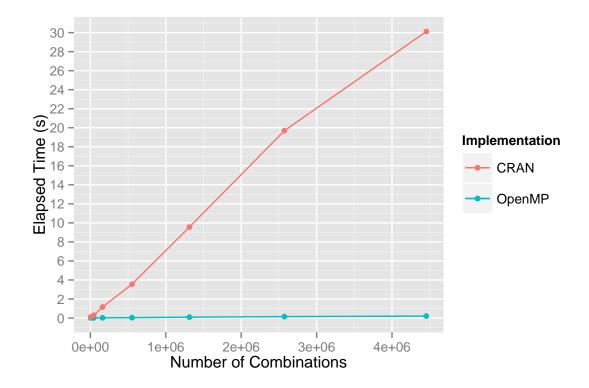

• Avoidance of critical sections and barriers (the only barrier is the implicit barrier at the end f the parallel pragma)

3.1.5 Comparative Analysis

The following input sizes were used for comparing the speeds of the source code and our OpenMP implementation using 8 threads set on the environment. The function nCm() is also from the CRAN "combinat" package. nCm() is the function that calculates the binomial coefficient ("n choose m") or the total number of combinations of size m given n elements. The third argument controls the rounding of the integers. [1]

The elapsed time that is recorded for each test is the average of three trials. The OpenMP parallelization massively improved the performance of the function. The improvement becomes increasingly invaluable as the input size increases (e.g. for nCm(100, 5), the OpenMP implementation still manages to produce an output under 5 seconds, while the original function takes several minutes).

The following plot illustrates the differences in the speeds of the two implementations.

3.2 Snow

The function combnsnow() accepts the same input arguments as the original function combn() from the CRAN package. combnsnow() can also handle the same types of valid inputs (see Section 2.1).

Usage:

```
combnsnow <- function(cls, x, m, fun = NULL, simplify = TRUE, ...)</pre>
```

where cls is the clusters, x is the input vector of integers and/or characters, m is number of elements per combination fun is the function to be applied to the resulting output, simplify indicates whether the output must be printed as a matrix (set to TRUE) or as a list (set to FALSE), and ... are the parameters for fun.

Code highlights:

• Load balancing algorithm implemented in R Snow

Other notes:

• Again, the program terminates if R decides that it cannot allocate enough space for the program to successfully run.

3.2.1 The Issue of Communication Overhead

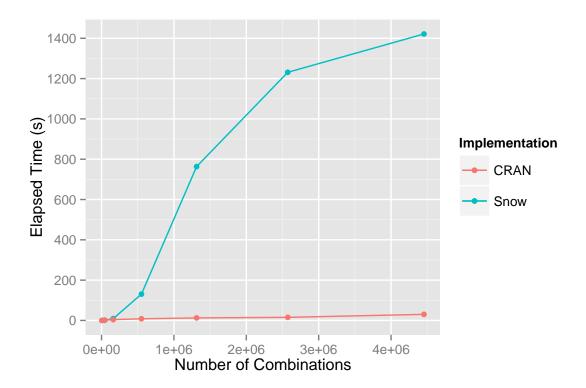

After running tests using small inputs, it was observed that parallelization using Snow more often than not took longer than running the CRAN function combn(). This is because of the communication overhead. The communication between the nodes in the cluster took more time than the actual computations in the function. If the jobs sent to the worker nodes are not relatively computationally extensive, the overhead of communicating ends up deteriorating the performance.

3.2.2 Reducing Network Overhead

Communication is much slower than computation. There is already communication overhead to setting up clusters. In order to reduce network overhead and improve the performance, the code was written so that the nodes will do long calculations, and the tasks are going to be pre-assigned so that there will be less communications among the nodes as each work on its own tasks. The same load balancing algorithm as in Section 3.1.1 was used to distribute the tasks to each nodes.

3.2.3 Comparative Analysis

The same input sizes and function arguments as in Section 3.1.5 were used for testing. For the Snow tests, 8 clusters were used. The following plot illustrates the differences in speeds between the Snow and CRAN implementations:

Despite our efforts to achieve speedups, the Snow implementation was actually much slower than the serial implementation of combn(). While the load balancing algorithm

helped in distributing the tasks, there are other aspects in the code that makes the program slower. For instance, sorting and formatting of the output is not in parallel, which can take a really long time in R when the input size is really big. There is also the inevitable communication overhead due to the use of clusters.

3.3 Thrust

The function combnthrust() accepts the same input arguments as the original function combn() from the CRAN package. combnthrust() can also handle the same types of valid inputs (see Section 2.1).

Usage:

```
combnthrust <- function(x, m, fun = NULL, simplify = TRUE, ...)</pre>
```

where x is the input vector of integers and/or characters, m is number of elements per combination fun is the function to be applied to the resulting output, simplify indicates whether the output must be printed as a matrix (set to TRUE) or as a list (set to FALSE), and ... are the parameters for fun.

Code highlights:

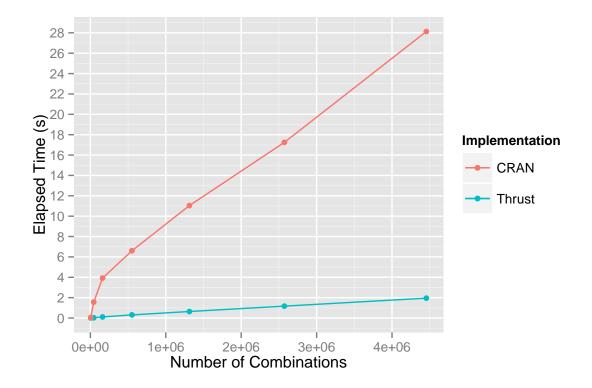

- We followed this tutorial [3] to link Rcpp, Thrust, and C++.
- We used Thrust's for_each function to call on the functor that finds the combination for each element, up to n - m + 1 in a parallel manner.

Other notes:

- The program terminates if Thrust is unable to allocate enough space on the GPU to have the program run successfully.
- Since Thrust calls are CUDA kernel calls, there is some latency involved in this, which slows the program down.
- Thrust uses shared memory because the CUDA backend utilizes the GPU and GPUs have shared memory.

3.4 Comparative Analysis

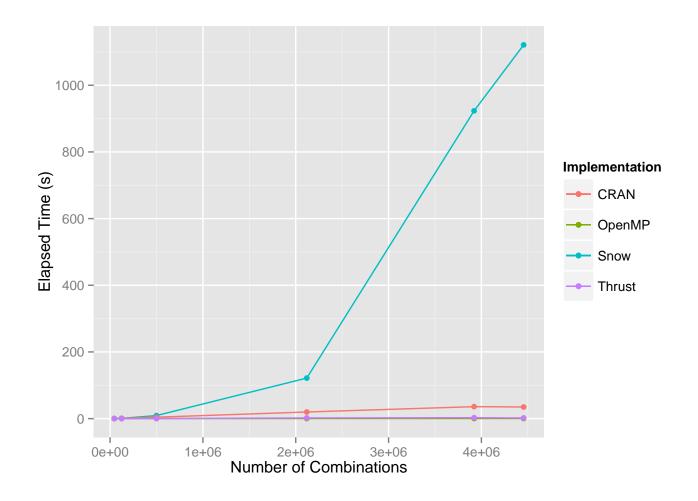

The same input sizes and function arguments as in Section 3.1.5 were used for testing Thrust. The following plot illustrates the differences in speeds between the Thrust and CRAN implementations:

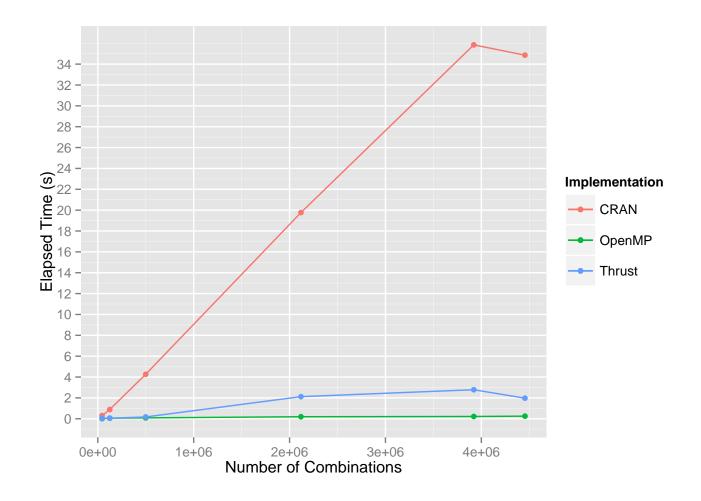

We were able to achieve speedup when using Thrust over the CRAN implementation for smaller input sizes of less than 600. Although the program terminated if the GPU could not allocate enough memory for large input sizes, Thrust was consistently faster than CRAN by using a functor. The program also modified the elements of the output matrix in parallel by making sure the indices didn't conflict.

4 Timing Comparisons and Analysis

The following plot compares all four implementations for various values of x and m. The number of clusters used for Snow and the number of threads used for OpenMP are both 8.

Clearly, the Snow implementation is simply too slow. By excluding Snow, we can have a closer look on the speeds of the other three implementations:

OpenMP and Thrust both massively improved the performance of combn() especially for large inputs. OpenMP was faster, and it also worked for even bigger inputs. We were able to get results for up to 75,287,520 combinations (nCm(100, 5)) in under 5 seconds. The differences in speeds between the OpenMP and Thrust implementations started to become quite significant at around 20,708,500 combinations (nCm(500, 3)). The Thrust program also started to have memory issues past this input size because of the limitations in the memory of the GPU. The speeds for OpenMP and Snow also didn't vary very significantly when using threads/nodes in the range of 6-10.

5 Conclusions

We expected Thrust to be the fastest out of the three parallel implementations of the combn() function, due to the GPU scheduling large number of threads. However, OpenMP was the fastest because we were able to efficiently divide the workload among the threads. Thrust ended up running slower than our OpenMP implementation, possibly due to Thrust dynamically scheduling the threads in the GPU. Thrust could have run faster if it was further optimized to reduce the amount of overhead by modifying our functor or incorporating other Thrust functions. As for Snow, we expected it to be much faster

especially with larger input since the communication overhead would have been hidden by the long calculations. However, Snow ended up performing the poorest, likely because there were also significant parts of the code that were not parallelized (sorting and handling of the output).

A Appendix

```
2 # R call function for the OpenMP parallelization of combn() from the CRAN
 3 # combinat package: http://cran.r-project.org/web/packages/combinat/index.html
5 # Function Arguments:
 6 # x <- input vector of integers and/or characters
7 # m <- number of elements in a combination
 8 # fun <- function to apply to the resulting output
9 # simplify <- if TRUE, print output as a matrix with m rows and nCm columns
10 # else <- print output as a list
   # nCm is the total number of combinations generated
12 # sched <- scheduling policy: static, dynamic, guided; default is static
13 # chunksize <- chunksize for scheduling policy; default is 1
14 # ... <- parameters for fun
16 # Helper functions for handling characters in input vector x:
17 # is.letter <- function to check if there's a char in x

157 # DATE WRITTEN: 7 June 1995
                                               LAST REVISED: 10 July 1995
158 # AUTHOR: Scott Chasalow
159 #
160 # DESCRIPTION:
161 #
            Compute the binomial coefficient ("n choose m"), where n is any
162 #
            real number and m is any integer. Arguments n and m may be vectors;
163 #
            they will be replicated as necessary to have the same length.
164 #
165 #
            Argument tol controls rounding of results to integers. If the
166 #
            difference between a value and its nearest integer is less than tol,
167 #
            the value returned will be rounded to its nearest integer. To turn
168 #
            off rounding, use tol = 0. Values of tol greater than the default
169 #
            should be used only with great caution, unless you are certain only
170 #
            integer values should be returned.

201
       # DESCRIPTION:
202
        # Compute the binomial coefficient ("n choose m"), where n is any
203
        # real number and m is any integer. Arguments n and m may be vectors;
204
        # they will be replicated as necessary to have the same length.
205
206
       # Argument tol controls rounding of results to integers. If the
207
        # difference between a value and its nearest integer is less than tol,
208
        # the value returned will be rounded to its nearest integer. To turn
209
        # off rounding, use tol = 0. Values of tol greater than the default
210
       # should be used only with great caution, unless you are certain only
211
        # integer values should be returned.

       DATE WRITTEN: 7 June 1995
                                                    LAST REVISED: 10 July 1995
132 # AUTHOR: Scott Chasalow
133 #
134 # DESCRIPTION:
135 #
             Compute the binomial coefficient ("n choose m"), where n is any
136 #
             real number and m is any integer. Arguments n and m may be vectors;
137 #
             they will be replicated as necessary to have the same length.
138 #
139 #
             Argument tol controls rounding of results to integers. If the
140 #
             difference between a value and its nearest integer is less than tol,
141 #
             the value returned will be rounded to its nearest integer. To turn
142 #
             off rounding, use tol = 0. Values of tol greater than the default
143 #
             should be used only with great caution, unless you are certain only
144 #
             integer values should be returned.
145 #

Account of Work Done

Trisha Funtanilla: I worked on the OpenMP implementation with Eva, putting together the Rcpp interface, error checks, and output formatting for the codes, writing the OpenMP and Snow section in the report, and creating the timing comparison plots.

Syeda Inamdar: I worked with Jennifer on the Thrust implementation and integrating the Rcpp file Trisha wrote to the Thrust interface. I also worked with Jennifer to write the Thrust section in the report and conduct timing comparisons.

Eva Li: I worked on the OpenMP and Snow implementations.

Jennifer Wong: I worked on the Thrust implementation, ran tests for the timing comparison plots for Trisha, and wrote the Thrust section in the report along with Syeda.
